We study self-excited oscillations (SEOs) in an on-fiber optomechanical cavity. While the phase of SEOs randomly diffuses in time when the laser power injected into the cavity is kept constant, phase locking may occur when the laser power is periodically modulated in time. We investigate the dependence of phase locking on the amplitude and frequency of the laser-power modulation. We find that phase locking can be induced with a relatively low modulation amplitude provided that the ratio between the modulation frequency and the frequency of SEOs is tuned close to a rational number of relatively low hierarchy in the Farey tree. To account for the experimental results, a one-dimensional map, which allows evaluating the time evolution of the phase of SEOs, is theoretically derived. By calculating the winding number of the one-dimensional map, the regions of phase locking can be mapped in the plane of modulation amplitude and modulation frequency. Comparison between the theoretical predictions and the experimental findings yields a partial agreement.

DOI: 10.1103/PhysRevE.93.023007

Optomechanical cavities [1–7] are widely employed for various sensing [8–11] and photonics [12–18] applications. Moreover, such systems may allow experimental study of the crossover between classical to quantum realms [3,19–28]. The effect of radiation pressure typically governs the optomechanical coupling (i.e., the coupling between the electromagnetic cavity and the mechanical resonator that serves as a movable mirror) when the finesse of the optical cavity is sufficiently high [3,5,23,29–31], whereas bolometric effects can contribute to the optomechanical coupling when optical absorption by the vibrating mirror is significant [4,32–39]. Generally, bolometric effects are dominant in systems consisting of relatively large mirrors, in which the thermal relaxation rate is comparable to the mechanical resonance frequency [36–38,40]. These systems [4,32,34,40–42] exhibit many intriguing phenomena such as mode cooling and self-excited oscillation (SEO) [2,22,34,37,40,43–46]. It has been recently demonstrated that optomechanical cavities can be fabricated on the tip of an optical fiber [47–57]. These micron-scale devices, which can be optically actuated [58], can be used for sensing physical parameters that affect the mechanical properties of the suspended mirror (e.g., absorbed mass, heating by external radiation, acceleration, etc.).

In a recent study [57], phase locking of SEOs has been investigated in an on-fiber optomechanical cavity formed between a fiber Bragg grating (FBG) mirror, serving as a static reflector, and a vibrating mirror, which is fabricated on the tip of a single-mode optical fiber. In that experiment [57] SEOs [8–11] were optically induced by injecting a monochromatic laser light into the on-fiber optomechanical cavity. The optically induced SEO is attributed to the bolometric optomechanical coupling between the optical mode and the mechanical resonator [41,42]. It was found in Ref. [57] that the phase of the SEO can be locked by periodically modulating the laser power that is injected into the cavity. Such phase locking results in entrainment [59–61], i.e., synchronization [62–64] between the SEO and the external modulation [65,66]. Synchronization in self-oscillating systems [63,67–72], in general, can be the result of interaction between systems [73–79], external noise [80–87], or other outside sources, periodic [88–90] or nonperiodic [91,92]. Synchronization can also be activated by applying a delayed feedback [93–96].

In the experiment reported in Ref. [57], phase locking [97–102] was studied for the case where the ratio between the modulation frequency and the frequency of SEO, which is henceforth labeled as \(1 - \alpha\), was tuned close to two values, the first value \(1 - \alpha = 1\) corresponds to modulation at the SEO frequency, and the second value \(1 - \alpha = 2\) corresponds to modulation at twice the SEO frequency. In the current paper we extend the study and investigate phase locking for arbitrary values of the dimensionless parameter \(\alpha\) in the range [0,1]. This is done by experimentally mapping the region of phase locking in the plane of the modulation amplitude and modulation frequency. We find that phase locking can be induced with relatively low modulation amplitude provided that \(\alpha\) is tuned close to a rational number of relatively low hierarchy in the Farey tree [103]. To account for the experimental results we theoretically evaluate the effect of modulation on the time evolution of the phase of SEO. Some simplifying assumptions and approximations lead to a one-dimensional map [Eq. (5), below], which describes the change that is accumulated over a single period of mechanical oscillation in the relative phase between SEO and the modulation, which is labeled by \(2\pi q\). The winding number of the one-dimensional map exhibits a Devil’s staircase (Fig. 2, below) [101,104–106], i.e., plateaus near rational values of the parameter \(\alpha\), corresponding to regions where phase locking [99,100] occurs. Partial agreement is obtained from the comparison between the experimental findings and theoretical predictions.

The optomechanical cavity, which is schematically shown in Fig. 1(a), was fabricated on the flat polished tip of a single-mode fused-silica optical fiber with outer diameter of 126 \(\mu\)m (Corning SMF-28 operating at a wavelength band around 1550 nm) held in a zirconia ferrule [56]. A 10-mm-thick chromium layer and a 200 nm gold layer were successively deposited by thermal evaporation. The bilayer was directly patterned by a focused ion beam to the desired mirror shape (20-\(\mu\)m-wide doubly clamped beam). Finally, the mirror was released by etching approximately 12 \(\mu\)m of the underlying silica in 7% HF acid (90 min. etch time at room temperature).
The suspended mirror remained supported by the zirconia ferrule, which is resistant to HF.

The static mirror of the optomechanical cavity was provided by a FBG mirror [41] (made by using a standard phase mask technique [107], with grating period of 0.527 μm and length ≈8 mm) having a reflectivity band of 0.4 nm full width at half maximum (FWHM) centered at 1545 nm. The length of the optical cavity was l ≈ 10 mm, providing a free spectral range of Δλ = λ0^2/(2n_eff l) ≈ 80 pm (where n_eff = 1.468 is the effective refraction index for SMF-28). Monochromatic light was injected into the fiber bearing the cavity on its tip from a laser source with an adjustable output wavelength λ and power level P_l. The laser was connected through an optical circulator, which allowed the measurement of the reflected light intensity I_r by using a photodetector (PD), connected to both a spectrum analyzer and an oscilloscope. The average laser power is set to 12 mW, the temperature of 77 K. The laser power and laser wavelength were first tuned into the regime of SEO before the modulation was turned on.

Phase locking was measured near all fractions α = n_1/n_2 in the range 0 < α < 1, where n_2 ∈ {1,2,3,4,5}. The case 1 − α = 2/3 is demonstrated in Fig. 1. The plot in Fig. 1(c) shows the measured signal of a spectrum analyzer, which is connected to the photodetector, vs the normalized modulation frequency 1 − α and the normalized measurement frequency ωSA/Ω_H, where Ω_H/2π = 236.3 kHz is the frequency of SEO. In the region of phase locking, near the point 1 − α = 2/3 the spectral peak corresponding to SEO coincides with the sideband corresponding to the power modulation. The other spectral lines in Fig. 1(c) converging to the central point 1 − α = 2/3 and ωSA/Ω_H = 1 represent higher-order products of frequency mixing between Ω_H and (1 − α)Ω_H [108].

The plot in Fig. 1(d) exhibits the measured probability distribution F(q) of the variable q, which represents the relative phase between SEO and the modulation in units of 2π. The distribution F(q) is extracted from the oscilloscope’s data by employing the zero-crossing technique [109]. While F(q) is found to have a nearly uniform distribution away from the point 1 − α = 2/3, three pronounced peaks are observed in the region of phase locking near that point, suggesting that the relative phase undergoes a limit cycle of period three.

To account for the experimental findings we theoretically investigate under what conditions phase locking of SEO is expected to occur. In the limit of small displacement, the dynamics of the system can be approximately described by using a single evolution equation [42,110].

The theoretical model that is used to derive the evolution equation [see Eq. (4), below] is briefly described below. Note that some optomechanical effects that were taken into account in the theoretical modeling [42] were found experimentally to have negligible effect on the dynamics [41] (e.g., the effect of radiation pressure). In what follows such effects are disregarded.

The micromechanical mirror in the optical cavity is treated as a mechanical resonator with a single degree of freedom x having mass m and linear damping rate γ_0 (when it is decoupled from the optical cavity). It is assumed that the angular resonance frequency of the mechanical resonator depends on the temperature T of the suspended mirror. For small deviation of T from the base temperature T_0 (i.e., the temperature of the supporting substrate) it is taken to be given by ω_0 − β(T − T_0) and where β is a constant. Furthermore, to model the effect of thermal deformation [34] it is assumed that a temperature-dependent force given by mθ(T − T_0), where θ is a constant, acts on the mechanical resonator [39].

When noise is disregarded, the equation of motion governing the dynamics of the mechanical resonator is taken to be given by

\[ \frac{d^2x}{dt^2} + 2\gamma_0 \frac{dx}{dt} + (\omega_0 - \beta T_R)^2 x = \theta T_R. \]  

(1)

The intracavity optical power incident on the suspended mirror is denoted by P_l I(λ), where P_l is the injected laser power, and the function I(λ) depends on the mechanical displacement x [see Eq. (3), below]. The time evolution of the relative temperature T_R is governed by the thermal balance
\[
\frac{dT_R}{dt} = Q - \kappa T_R,
\]
where \( Q = \eta P_L I(x) \) is proportional to the heating power, \( \eta \) is the heating coefficient due to optical absorption, and \( \kappa \) is the thermal decay rate.

The function \( I(x) \) depends on the properties of the optical cavity that is formed between the suspended mechanical mirror and the on-fiber static reflector. The finesse of the optical cavity is limited by loss mechanisms that give rise to optical energy leaking out of the cavity. The main escape routes are through the on-fiber static reflector, through absorption by the metallic mirror, and through radiation. The corresponding transmission probabilities are respectively denoted by \( T_B \), \( T_A \), and \( T_R \).

In terms of these parameters, the function \( I(x) \) is given by

\[
I(x) = \frac{\beta_F (1 - \beta_F^2) \beta_F^2}{1 - \cos \frac{4\pi x_D}{\lambda} + \beta_F^2},
\]

where \( x_D = x - x_R \) is the displacement of the mirror relative to a point \( x_R \), at which the energy stored in the optical cavity in steady state obtains a local maximum, \( \beta_F^2 = (T_R \pm T_A \pm T_B)^2/8 \) and where \( \beta_F \) is the cavity finesse. The reflection probability \( R_C = P_R/P_L \) is given in steady state by \( R_C = 1 - I(x)/\beta_F \). For sufficiently small \( x \), the expansion \( I(x) \approx I_0 + I_0' x + (1/2) I_0'' x^2 + O(x^3) \) can be employed, where a prime denotes differentiation with respect to the displacement \( x \).

Consider the case where the laser power \( P_L \) is modulated in time according to \( P_L(t) = P_0 + P_1(t) \), where \( P_0 \) is a constant and \( P_1(t) \) is assumed to have a vanishing average. When both \( P_1 \) and \( I - I_0 \) are sufficiently small, the problem can be significantly simplified by employing the approximation \( Q \approx \eta P_0 I + \eta P_1 I_0 \). The displacement \( x(t) \) is expressed in terms of the complex amplitude \( A \) as

\[
x(t) = x_0 + 2 \text{Re} A,
\]

where \( x_0 \), which is given by

\[
x_0 = \frac{\eta \theta P_0 I_0}{(\kappa \omega_0)^2},
\]

is the averaged optically induced static displacement. For a small displacement, the evolution equation for the complex

\[
f_{\alpha}(q) = f_{\alpha}(q)
\]

\[
F(q) = F(q)
\]

\[
V_{PD}[V] = V_{PD}[V]
\]

FIG. 2. The winding number and limit cycles. (a) Devil’s staircase in the plot of the winding number \( W \) vs \( \alpha \) for the case where \( \beta_F = 0.0355 \). Locally stable limit cycles for the case \( 1 - \alpha = 2/3 \) and \( \beta_F = 0.025 \) are presented in panels (b), (d), and (f) and for the case \( 1 - \alpha = 3/5 \) and \( \beta_F = 0.028 \) in panels (c), (e), and (g). The map \( f_{\alpha}(q) \) together with the corresponding limit cycle for the case \( 1 - \alpha = 2/3 \) (1 - \( \alpha = 3/5 \) is depicted in panel (b) [panel (c)], the experimentally measured probability distribution \( F(q) \) in panel (d) [panel (e)], and a sample temporal data in panel (f) [panel (g)] (the vertical lines label the beginning points of each modulation period). In the experimental measurements presented in this plot a pulse-power modulation having a rectangular (instead of a sinusoidal) waveform has been employed. For that case, the recursive relation \( q_{n+1} = f_{\alpha}(q_n) \) is derived by first performing a Fourier decomposition of the rectangular waveform, and then calculating the contribution of each Fourier component by using Eq. (6).
amplitude $A$ is found to be given by [42,57]
\begin{equation}
\dot{A} + (\Gamma_{\text{eff}} + i\Omega_{\text{eff}})A = \xi(t) + \vartheta(t),
\end{equation}
where both the effective resonance frequency $\Omega_{\text{eff}}$ and the effective damping rate $\Gamma_{\text{eff}}$ are real even functions of $|A|$. To second order in $|A|$ they are given by $\Gamma_{\text{eff}} = \Gamma_0 + \Gamma_2|A|^2$ and $\Omega_{\text{eff}} = \Omega_0 + \Omega_2|A|^2$, where $\Gamma_0 = \gamma_0 + \eta \theta P_i \omega_0/(2\alpha_0^2)$, $\Gamma_2 = \gamma_2 + \eta \beta P_i \omega_0/(4\alpha_0^2)$, with $\gamma_2$ being the intrinsic mechanical nonlinear quadratic damping rate [112], $\Omega_0 = \omega_0 - \eta \beta P_i \omega_0/k$, and $\Omega_2 = -\eta \beta P_i \omega_0/k$. Note that the above expressions for $\Gamma_{\text{eff}}$ and $\Omega_{\text{eff}}$ are obtained by making the following assumptions: $\kappa^2/(\omega_0^2\lambda) \ll \beta/\theta \ll 1/(2\omega_0\kappa_0)$ and $\kappa \ll \omega_0$, both typically hold experimentally [41]. The term $\xi(t)$, which is given by $\xi(t) = \Omega_0^{-1}\partial T_{K1}(t)$, where $T_{K1}(t)$ is found by solving Eq. (2) for the case where the the laser power is taken to be $P_i(t)$, represents the thermal force that is generated due to the power modulation. The fluctuating term [113,114] $\vartheta(t) = \theta_1(t) + i\theta_2(t)$, where both $\theta_1$ and $\theta_2$ are real, represents white noise and the following is assumed to hold: $\langle \theta_1(t)\theta_2(\tau') \rangle = \langle \theta_1(t)\theta_1(\tau') \rangle = \langle 2\theta_1(t-\tau') \rangle$ and $\langle \theta_1(t)\theta_2(\tau') \rangle = 0$, where $\Theta = \gamma_2 k_0 T_{\text{eff}}/(4m\omega_0^2)$. $k_0$ is Boltzmann’s constant, and $T_{\text{eff}}$ is the effective noise temperature.

In the absence of laser modulation, i.e., when $P_1 = 0$, the equation of motion (4) describes a van der Pol oscillator [98]. Consider the case where $\Gamma_2 > 0$, for which a supercritical Hopf bifurcation occurs when the linear damping coefficient $\Gamma_0$ vanishes. Above threshold, i.e., when $\Gamma_0$ becomes negative, the amplitude $A_i = |A|$ of SEOs is given by $A_{i\omega} = \sqrt{-\Gamma_0/\Gamma_2}$ and the angular frequency $\Omega_{i\omega}$ of SEOs by $\Omega_{i\omega} = \Omega_{\text{eff}}(A_{i\omega})$. For our experimental parameters $|\Omega_2| \ll \omega_0|A_{i\omega}|$, and consequently to a good approximation the dependence of $\Omega_{i\omega}$ on $A_{i\omega}$ can be disregarded.

The laser-power modulation $P_i(t)$ is taken to be time periodic with angular frequency $(1-\alpha)\Omega_{i\omega}$, a sinusoidal waveform and an amplitude $P_0\alpha$, which is expressed as $P_i = \beta_i \Omega_{i\omega} A_{i\omega}/(\theta \eta I_0)$, where both $\alpha$ and $\beta_i$ are real dimensionless constants. Let $2\pi q_n$ be the relative phase of SEO with respect to the external modulation after an integer number $n$ of periods of mechanical oscillation. Integrating Eq. (4) over a single period of SEO (and disregarding the noise term) yields for the case where $\beta_i \ll 1$ a recursive relation between $q_{n+1}$ and $q_n$ which reads
\begin{equation}
q_{n+1} = f_\alpha(q_n),
\end{equation}
where
\begin{equation}
f_\alpha(q) = q + \alpha + \frac{2\beta_1 \sin(\pi \alpha) \cos(\pi \alpha + 2\pi q)}{(1-\alpha)[1-(1-\alpha)^2]}.
\end{equation}

The winding number $W$ is defined by [101]
\begin{equation}
W = \lim_{n \to \infty} \frac{q_{n+1} - q_1}{n}.
\end{equation}

For the case of a limit cycle, the winding number is a rational number given by $W = n_1/n_2$, where $n_2$ is the period of the cycle and $n_1$ is the number of sweeps through the unit interval [0,1] in a cycle when the mapping (6) is considered as modulo 1. The Devil’s staircase can be seen in Fig. 2(a), in which the winding number $W$ is plotted as a function of $\alpha$ for the case where $\beta_i = 0.0355$. Locally stable limit cycles are presented in Fig. 2 for the case $1-\alpha = 2/3$ and $\beta_i = 0.025$ [Figs. 2(b), 2(d), and 2(f)] and for the case $1-\alpha = 3/5$ and $\beta_i = 0.028$ [Figs. 2(c), 2(e), and 2(g)]. The map $f_\alpha(q)$ together with the corresponding limit cycle for the case $1-\alpha = 2/3$ ($1-\alpha = 3/5$) is depicted in Fig. 2(b) [Fig. 2(c)], the experimentally measured probability distribution $F(q)$ in Fig. 2(d) [Fig. 2(e)], and a sample of temporal data in Fig. 2(f) [Fig. 2(g)]. The comparison between the values of $q$ corresponding to the peaks in the measured distribution $F(q)$ [Figs. 2(d) and 2(e)] and the values of $q$ corresponding to the calculated limit cycle [Figs. 2(b) and 2(c)] exhibits a partial agreement.

Regions of phase locking in the plane that is spanned by the modulation parameters (frequency and amplitude) are commonly called Arnold tongues. The Arnold tongue near $\alpha = 1/2$ is seen in Fig. 3. The color map presents the measured value of the derivative $dW/d\alpha$ vs $\alpha$ and $\beta_i$. The black dotted line represents the theoretically calculated bifurcation line $\beta_i = (81/128\pi)^{1/3}(1-1/2)^{1/5}$. Laser parameters are the same as those listed in the caption of Fig. 1. The experimental value of the dimensionless parameter $\beta_i$ is determined by using the following device parameter: $\Omega_{i\omega}A_{i\omega}/(\theta \eta I_0) = 0.10$ W.
be employed as a sensor operating in the region of SEO. Future study will address the possibility of reducing phase noise by inducing phase locking in order to enhance sensor’s performance.
